Case Report of a Challenging Diagnosis of Nasal Tuberculosis

Caso Clínico de um Diagnóstico Desafiante de Tuberculose Nasal

Dear Editor,

The incidence of tuberculosis (TB) has been steadily declining for the past two decades. However, since the beginning of the COVID-19 pandemic, the TB incidence rate is estimated to have increased.1

Although western Europe is considered a low TB incidence region, recent migration trends have called attention to its ongoing relevance, since ear, nose, and throat (ENT) manifestations, such as nasal and nasopharyngeal tuberculosis, are rare.2

We describe a clinical case of a 77-year-old white man presenting to the ENT clinic with a two-week history of right nasal obstruction and localized pain. Anterior rhinoscopy revealed a friable, erythematous crusting of the anterior right septal mucosa. A biopsy was done showing inflammatory exudate, ulceration, and no evidence of malignancy. The patient started oral antibiotics and corticosteroids, with limited improvement.

At re-assessment, an anterior septal friable perforation was seen, and a paranasal sinus computed tomography (CT) scan revealed thickening of the nasal vestibule and anterior nasal septum with irregularity of the right mucosa and septal perforation. Paranasal sinuses were clear and pneumatized. No bone lesions were found. Punch biopsy of the septal ulcer was repeated, confirming the ulcerative granulomatous lesion with caseating necrosis without vasculitic nor neoplastic features (Fig. 1A). No microorganisms were found.

An immune panel, a klebsiella nasal swab and an HIV test were negative.

At this point, a review of the patient’s medical history disclosed an episode of ganglionar tuberculosis 30 years ago. The patient denied fever, weight loss or night sweats and chest CT was normal. The histopathologic review of the tissue sample taken previously was required and staining with Ziehl-Neelsen was positive for acid-alcohol resistant bacilli. The polymerase chain reaction (PCR) and culture test were positive for Mycobacterium tuberculosis (Fig. 1B).

The patient started antitubercular therapy with isoniazid, rifampin, ethambutol and pyrazinamide for four months, followed by two months of isoniazid and rifampin.

At the first- evaluation one month following treatment, the patient was clinically improved. Anterior septal perforation remained, which resulted in nasal tip ptosis.

Nasal tuberculosis is a rare entity, and clinical presentation with ulcerative and destructive features can mimic malignancy, emphasizing not only the need for biopsy, but also routine microbiology and appropriate culture tests, so that infectious causes are not overlooked, and treatment is not delayed.

The diagnosis is difficult, especially because it requires a high diagnostic suspicion and histological confirmation is hampered by lengthy and false negative results. In fact, smears of acid-fast bacilli and cultures tend to be negative in nasal tuberculosis.

Given the recent reversal in TB prevalence trends worldwide, physicians should bear in mind that, even though nasal tuberculosis is a challenging diagnosis, new diagnostic tools such as PCR or interferon-γ assay can be extremely useful to achieve prompt results.3

Dear Editor,

*Staphylococcus argenteus* is a novel species described in 2015, belonging to a divergent *Staphylococcus aureus* lineage. Since then, the detection of *S. argenteus* infections increased worldwide, although it remains distinguished from *S. aureus* by standard non-molecular methods. In December 2021, a 71-year-old man was admitted to the intensive care unit with respiratory failure associated with COVID-19 pneumonia. On day six of intubation, the tracheal aspirate was collected after the detection of purulent sputum associated with fever and increased systemic inflammatory markers.

At the microbiology laboratory, the bacteriological examination revealed a non-pigmented and greyish creamy colony with beta-haemolysis on blood agar (Fig. 1A) and a positive coagulase agglutination test. A putative *Staphylo-

coccus aureus* was initially identified (labelled as ULSM26) through the automated identification systems VITEK®MS (bioMérieux) and susceptibility testing was performed on Vitek®2 (bioMérieux) with the AST-P648 card. Penicillin and vancomycin susceptibility were assessed by disc diffusion and the agar gradient test, respectively, according to the EUCAST breakpoints. The genetic background of ULSM26 was assessed by spa typing and detection of *mecA*, *pvl* and other virulence determinants were carried out by PCR. A methicillin-susceptible *S. aureus* (MSSA), with non-multiresistant profile, except to penicillin and tetracycline, was reported and the patient received ceftiraxone with a favourable clinical evolution.

Molecular characterization identified a spa type t5078, associated with clonal complex 75 and suggestive of a *Staphylococcus argenteus* species, which was confirmed by NRPS gene amplification (Fig. 1B). Neither *mecA*, *pvl*, or other virulence genes were detected on USLM26, except the staphylococcal immune evasion cluster genes *sak* (staphylokinase) and *scn* (staphylococcal complement inhibitor).

Previous studies suggest that the frequency of healthcare-associated infections, morbidity and mortality are comparable to those of *S. aureus*. Although resistance rates seem to be lower in *S. argenteus*, penicillin-resistant strains are common and methicillin resistance is prevalent in Europe and Australia. Furthermore, a wide variety of virulence.
